Improving approximate Bayesian computation via quasi Monte Carlo

Alexander Buchholz    Nicolas Chopin
ENSAE-CREST

Abstract

ABC (approximate Bayesian computation) is a general approach for dealing with models with an intractable likelihood. In this work, we derive ABC algorithms based on QMC (quasi-Monte Carlo) sequences. We show that the resulting ABC estimates have a lower variance than their Monte Carlo counter-parts. We also develop QMC variants of sequential ABC algorithms, which progressively adapt the proposal distribution and the acceptance threshold. We illustrate our QMC approach through several examples taken from the ABC literature.

Keywords: Approximate Bayesian computation, Likelihood-free inference, Quasi Monte Carlo, Randomized Quasi Monte Carlo, Adaptive importance sampling

1 Introduction

Since its introduction by Tavaré et al. (1997) approximate Bayesian computation (ABC) has received growing attention and has become today a major tool for Bayesian inference in settings where the likelihood of a statistical model is intractable but simulations from the model for a given parameter value can be generated. The approach of ABC is as convincing as intuitive: We first sample a value from the prior distribution, conditional on this prior simulation an observation from the model is generated. If the simulated observation is sufficiently close to the observation that has been observed in nature, we retain the simulation from the prior distribution and assign it to the set of posterior simulations. Otherwise the simulation is discarded. We repeat this procedure until enough samples have been obtained.

Since then several computational extensions related to ABC have been proposed. For instance the use of MCMC as by Marjoram et al. (2003) has improved the simulation of ABC posterior samples over the simple accept–reject algorithm. The use of sequential approaches by Beaumont et al. (2009), Sisson et al. (2009), Del Moral et al. (2012) and Sedki et al. (2012) made it possible to exploit the information from previous iterations and eventually to choose adaptively the schedule of thresholds $\epsilon$. Besides the question of an efficient simulation of high posterior probability regions, the choice of summary statistics, summarizing the information contained in the observation and the simulated observation, has been investigated (Fearnhead and Prangle, 2012). See Marin et al. (2012) and Lintusaari et al. (2017) for two recent reviews. Moreover, the introduction of more machine learning driven approaches like random forests (Marin et al., 2016) Gaussian processes (Wilkinson, 2014), Bayesian optimization (Gutmann and Corander, 2016), expectation propagation (Barthelmé and Chopin, 2014) and neural networks (Papamakarios and Murray, 2016) have been proposed. A post-processing approach via kernel density estimation was studied in Blum (2010).

In this paper we take a different perspective and approach the problem of reducing the variance of ABC estimators. We achieve this by introducing so called low discrepancy sequences in the
simulation of the proposal distribution. We show that this allows to reduce significantly the variance of posterior estimates.

The rest of the paper is organized as follows. Section 2 reviews the basic ideas of approximated Bayesian computation and sets the notation. Section 3 introduces the concept of low discrepancy sequences. Section 4 brings the introduced concepts together and provide the theory that underpins the proposed idea. Section 5 presents a first set of numerical examples. Section 6 explains how to use our ideas in a sequential procedure which adapts progressively the proposal distribution and the value of $\epsilon$. Section 6 illustrates the resulting sequential ABC procedure.

2 Approximate Bayesian computation

2.1 Reject-ABC

Approximate Bayesian computation is motivated by models such that (a) the likelihood function is difficult or expensive to compute; (b) simulating from the model (for a given parameter $\theta$) is feasible.

The most basic ABC algorithm is called reject-ABC. It consists in simulating pairs $(\theta, y)$, from the prior $p(\theta)$ times the likelihood $p(y|\theta)$, and keep those pairs such that $\delta(y, y^*) \leq \epsilon$, where $y^*$ is the actual data, and $\delta : \mathcal{Y} \times \mathcal{Y} \rightarrow \mathbb{R}^+$ is some distance (e.g. Euclidean). The target distribution of this rejection algorithm is:

$$p_{\epsilon}(\theta, y) = \frac{1}{Z_{\epsilon}} p(\theta) p(y|\theta) \mathbf{1}\{\delta(y, y^*) \leq \epsilon\},$$

and its marginal distribution with respect to $\theta$ is:

$$p_{\epsilon}(\theta) = \frac{1}{Z_{\epsilon}} p(\theta) \mathbb{P}_\theta (\delta(y, y^*) \leq \epsilon)$$

(1)

where $\mathbb{P}_\theta$ denotes a probability with respect to $y \sim p(y|\theta)$, and $Z_{\epsilon} = \int_{\Theta} p(\theta) \mathbb{P}_\theta (\delta(y, y^*) \leq \epsilon) d\theta$ is the normalising constant.

As $\epsilon \rightarrow 0$, (1) converges to the true posterior distribution. Actually, $\delta$ is often not a distance but a pseudo-distance of the form: $\delta(y, y^*) = \|s(y) - s(y^*)\|_2$, where $\|\cdot\|_2$ is the Euclidean norm, and $s(y)$ is a low-dimensional, imperfect summary of $y$. In that case, $p_{\epsilon}(\theta) \rightarrow p(\theta)s(y^*)$. This introduces an extra level of approximation, which is hard to assess theoretically and practically. However, in this paper we focus on how to approximate well (1) for a given $\delta$ (and $\epsilon$), and we refer to e.g. Fearnhead and Prangle (2012) for more discussion on the choice of $\delta$ or $s$.

2.2 Pseudo-marginal importance sampling

A simple generalisation of reject-ABC is described in Algorithm 1. For $n = 1, \ldots, N$, we sample the parameter $\theta_n \sim q(\theta)$, the latent variable $x_n \sim q_{\theta_n}(x)$, and reweight $(\theta_n, x_n)$ according to

$$w_n = \frac{p(\theta_n)}{q(\theta_n)} \times \hat{L}_\epsilon(x_n)$$

where, for $x \sim q_{\theta}$, $\hat{L}_\epsilon(x)$ is an unbiased estimate of the probability $\mathbb{P}_\theta (\delta(y, y^*) \leq \epsilon)$:

$$\int q_{\theta}(x) \hat{L}_\epsilon(x) dx = \mathbb{P}_\theta (\delta(y, y^*) \leq \epsilon).$$
However, the generalized scheme allows us (a) to sample $N$ that more likely (than the prior) to generate high values for the probability $P$ marginal sampler, in the spirit of Andrieu and Roberts (2009). The whole procedure may be viewed as a pseudo-importance weight involves an unbiased estimator, the whole procedure may be viewed as a pseudo-

The invariant distribution of this kernel is such that, marginally, the quantity $\theta$ is distributed according to (1); however this invariant distribution differs from the target distribution of our importance sampler.

Regarding (b), we consider two unbiased schemes in this work. In the first part, we focus on:

$$x = y_1:M, \quad q\theta(x) = \prod_{m=1}^{M} p(y_m|\theta), \quad \hat{L}_\epsilon(x) = \frac{1}{M} \sum_{m=1}^{M} \mathbb{1}\{d(y_m, y^*) \leq \epsilon\}.$$  

for a certain $M \geq 1$. The possibility to associate more than one datapoint to each parameter $\theta_n$ was considered in e.g. Del Moral et al. (2012). Bornn et al. (2015) showed that $M = 1$ usually represents the best variance vs CPU time trade-off when using Monte Carlo sampling, however we shall see that this result does not hold when using QMC.

Later on in the paper, we shall consider an alternative unbiased estimator, based on properties of the negative binomial distribution. More precisely, assume that, for a given $\theta$, we sample sequentially $y_1, y_2, \ldots \sim p(y|\theta)$, until we reach the time $k$ where $r \geq 2$ datapoints are such that $\delta(y_n, y^*) \leq \epsilon$; then $k$ is distributed according to a negative binomial distribution with parameters $r$ and $p = P_{\theta} (\delta(y, y^*) \leq \epsilon)$, and the minimum-variance unbiased estimator of $P_{\theta} (\delta(y, y^*) \leq \epsilon)$ is (Johnson et al., 2005 Chap. 8):

$$\hat{L}_\epsilon(x) = \frac{r - 1}{k - 1}$$

where $x = y_{1:k}$.

The second unbiased estimator is closely related, but not equivalent to, the $r$-hit kernel of Lee (2012); see also Lee and Łatuszyński (2014). Specifically, Lee (2012) proposed a MCMC kernel that generates two negative binomial variates (one for the current point, and one for the proposed point) at each iteration. The invariant distribution of this kernel is such that, marginally, $\theta$ is distributed according to (1); however this invariant distribution differs from the target distribution of our importance sampler.
In more practical terms, we shall use the latter estimator in situations where we would like to set \( \epsilon \) beforehand to some value such that \( \mathbb{P}_\theta (\delta(y, y^*) \leq \epsilon) \) may be small. In that case, this estimator automatically adjusts the CPU budget (i.e., the number of simulations from the likelihood) so as to ensure that the number of simulated \( y \)-values is non-zero. But we shall return to this point in Section \( \text{6} \).

3 Quasi Monte Carlo

Low discrepancy sequences (also called quasi Monte Carlo sequences), are used to approximate integrals over the \([0,1]^d\) hypercube:

\[
\mathbb{E} [\psi(U)] = \int_{[0,1]^d} \psi(u) du,
\]

that is the expectation of the random variable \( \psi(U) \), where \( U \sim \mathcal{U}([0,1]^d) \). The basic Monte Carlo approximation of the integral is \( \hat{I}_N = \frac{1}{N} \sum_{n=1}^N \psi(u_n) \), where each \( u_n \sim \mathcal{U}([0,1]^d) \). The error of this approximation is \( O_P(N^{-1/2}) \), since \( \text{Var}[\hat{I}_N] = \text{Var}[\psi(U)]/N \).

It is possible to improve on this basic approximation, by replacing the random variables \( u_n \) by a low-discrepancy sequence; that is, informally, a deterministic sequence that covers \([0,1]^d\) more regularly. This idea is illustrated in Figure 1.

More formally, the general notion of discrepancy of a given sequence is defined as follows:

\[
D(u_{1:N}, A) := \sup_{A \in \mathcal{A}} \left| \frac{1}{N} \sum_{n=1}^N \mathbb{1} \{u_n \in A\} - \lambda_d(A) \right|,
\]

where \( \lambda_d(A) \) is the volume (Lesbegue measure on \( \mathbb{R}^d \)) of \( A \) and \( \mathcal{A} \) is a set of measurable sets. When we fix the sets \( A \) to be intervals anchored at 0 we obtain the so called star discrepancy:

\[
D^*(u_{1:N}) := \sup_{[0,b]} \left| \frac{1}{N} \sum_{n=1}^N \mathbb{1} \{u_n \in A\} - \lambda_d(A) \right|,
\]

where \([0,b] = \prod_{i=1}^d [0,b_i], 0 \leq b_i \leq 1\). The importance of the notion of discrepancy and in particular the star discrepancy is highlighted by the Koksma-Hlawka inequality, which relates the error of the integration to the coverage of the space and the variation of the function that is integrated:

\[
\left| \int_{[0,1]^d} \psi(u) du - \frac{1}{N} \sum_{n=1}^N \psi(u_n) \right| \leq V(\psi) D^*(u_{1:N}),
\]

where \( V(\psi) \) is the variation in the sense of Hardy and Krause. This quantity is closely linked to the smoothness of the function \( \psi \); see [Knüers and Niederreiter (2012) and Leobacher and Pillichshammer (2014)] for more details.

It is possible to construct sequences \( u_n \) such that, when \( N \) is fixed in advance, \( D^*(u_{1:N}) \) is \( O\left( N^{-1}(\log N)^d\right) \), and, when \( N \) is allowed to grow, i.e., the sequence can be generated iteratively, then \( D^*(u_{1:N}) = O\left( N^{-1}(\log N)^d\right) \). Then \( \forall \tau > 0 \) the error rate is \( O\left( N^{-1+\tau}\right) \). Consequently, QMC integration schemes are asymptotically more efficient than MC schemes. One observes in practice that QMC integration outperforms MC integration even for small \( N \) in most applications, see e.g., the examples in Chapter 5 of [Glasserman (2013)].
3.1 Randomized quasi Monte Carlo

A drawback of QMC is that it does not come with an easy way to assess the approximation error.

RQMC (randomized quasi Monte Carlo) amounts to introduce randomness in a QMC sequence, in such a way that \( u_n \sim U([0, 1]^d) \), marginally. The quantity \( \hat{I}_N = N^{-1} \sum_{n=1}^{N} \psi(u_n) \) then becomes an unbiased estimate of the integral of interest. One may assess the approximation error by computing the empirical variance over repeated simulations.

The simplest way to obtain a RQMC sequence is to randomly shift a QMC sequence: Let \( v \sim U([0, 1]^d) \), and \( u_{1:N} \) a QMC sequence; then
\[
\hat{u}_n := u_n + v \mod 1 \text{ (component wise)}
\]
is a RQMC sequence.

A more sophisticated approach, called scrambled nets, was introduced by Owen (1997) and later refined in Owen et al. (2008). The main advantage of this approach is that under the assumption of smoothness of the derivatives of the function, the speed of convergence can be even further improved, as stated in the following Theorem.

\textbf{Theorem 1} Owen et al. (2008) Let \( f : [0, 1]^d \rightarrow \mathbb{R} \) be a function such that its cross partial derivatives up to order \( d \) exist and are continuous, and let \( (u_n)_{n \in 1:N} \) be a relaxed scrambled \((\lambda, t, m, d)\)-net in base \( b \) with dimension \( d \) with uniformly bounded gain coefficients. Then,
\[
\text{Var} \left( \frac{1}{N} \sum_{n=1}^{N} f(u_n) \right) = \mathcal{O} \left( N^{-3} \log(N)^{(d-1)} \right),
\]
where \( N = \lambda b^m \).

In words, \( \forall \tau > 0 \) the RQMC error rate is \( \mathcal{O}(N^{-3/2+\tau}) \) when a scrambled \((\lambda, t, m, d)\)-net is used. This result has the only inconvenience that the rate of convergence only holds for certain \( N \). However, a more general result has recently been shown by Gerber (2015) [Corollary 1], where if \( f \in L^2 \) and \( (u_n)_{n \in 1:N} \) is a scrambled \((t, d)\)-sequence, then \( \forall N \in \mathbb{N} \),
\[
\text{Var} \left( \frac{1}{N} \sum_{n=1}^{N} f(u_n) \right) = o \left( N^{-1} \right).
\]
3.2 Mixed sequences and a central limit theorem

One drawback of low discrepancy sequences is that the speed of convergence deteriorates with the dimension. In some situations, a small number of components contributes significantly to the variance of the target. One then might choose to use a low discrepancy sequence for those components and an ordinary Monte Carlo approach on the rest. This idea of using a mixed sequence is closely linked to the concept of effective dimension, see Owen (1998). Based on the randomness induced by the Monte Carlo part a central limit theorem (CLT) may be established:

**Theorem 2** Ökten et al. (2006) Let $u_k = (q_k^{1:d}, X_k^{d+1:s})$ be a mixed sequence of dimension $s$ where $q_k^{1:d}$ denotes the deterministic QMC part and $X_k^{d+1:s}$ denotes the random independent MC part. Let $f : [0, 1]^s \rightarrow \mathbb{R}$, $t \in \mathbb{N}^*$ a bounded, square integrable function, $Y_k = f(u_k)$, $\hat{I}_N = N^{-1} \sum_{k=1}^N Y_k$, and

\[ \mu_k := \mathbb{E}[Y_k] = \int_{[0,1]^{s-d}} f(u_k) dX^{d+1:s}, \]
\[ S_N := \frac{1}{N} \left( \sum_{k=1}^N Y_k - \sum_{k=1}^N \mu_k \right) = \left( \hat{I}_N - \frac{1}{N} \sum_{k=1}^N \mu_k \right), \]
\[ \sigma_k^2 := \text{Var}[Y_k] = \int_{[0,1]^{s-d}} f(u_k) f(u_k)^T dX^{d+1:s} \]
\[ - \left( \int_{[0,1]^{s-d}} f(u_k) dX^{d+1:s} \right) \left( \int_{[0,1]^{s-d}} f(u_k) dX^{d+1:s} \right)^T, \]
\[ C_N^2 := \text{Var}[N \hat{I}_N] = \sum_{k=1}^N \sigma_k^2. \]

Then, as $N \rightarrow +\infty$, $C_N^2 / N \rightarrow C^{\text{qmc-mixed}}$ and

\[ N^{1/2} S_N \xrightarrow{L} \mathcal{N}(0, C^{\text{qmc-mixed}}_N), \]

where

\[ C^{\text{qmc-mixed}}_N = \int_{[0,1]^s} f(x) f(x)^T dx \]
\[ - \left( \int_{[0,1]^{s-d}} f(u) dX^{d+1:s} \right) \left( \int_{[0,1]^{s-d}} f(u) dX^{d+1:s} \right)^T d\mathbf{q}^{1:d}. \]

As a direct corollary of the previous Theorem we obtain that, provided $f$ has a finite variation in the sense of Hardy and Krause, $N^{1/2}(\hat{I}_N - I) \xrightarrow{L} \mathcal{N}(0, C^{\text{qmc-mixed}}_N)$, where $I = \int f(u) du$. This is due to the fact that

\[ N^{1/2} (\hat{I}_N - I) = N^{1/2} S_N + N^{1/2} \left( \frac{1}{N} \sum_{k=1}^N \mu_k - I \right) \]

and the second term on the right hand side converges deterministically to 0. In their work Ökten et al. (2006) present only a univariate version of their central limit theorem, but the multivariate extension is straightforward.

As a direct corollary their work shows that the asymptotic variance of the mixed sequence estimator is smaller than for the same estimator based on Monte Carlo sequences in dimension one. We extend this result to the multivariate case.
Corollary 1 Let $C_{qmc-mixed}^2$ be the asymptotic variance of an estimator based on a mixed sequence as defined in Theorem 2. Let $C_{mc}^2$ be the variance of the same estimator based on a pure MC sequence, e.g., when $d = 0$. Then

$$C_{qmc-mixed}^2 \preceq C_{mc}^2$$

in the sense of positive definite matrices.

Moreover, we present a result here that allows us to apply the same technique to mixed sequences that combine Monte Carlo and randomized quasi Monte Carlo sequences.

Theorem 3 Let $S_{N}^{RQMC}$ be the MC-RQMC equivalent of $S_N$ under the same conditions as in Theorem 2. Then

$$N^{1/2} S_{N}^{RQMC} \xrightarrow{L} N(0, C_{qmc-mixed}^2)$$

where $C_{qmc-mixed}^2 = C_{qmc}^2 - \text{mixed}$. These results may be understood as follows. The randomness in the Monte Carlo sequence allows the construction of a central limit theorem. The part associated to the (R)QMC sequences converges faster to zero than the part associated to the Monte Carlo sequence. This leads to a reduced asymptotic variance for estimators based on mixed sequences.

4 Improved ABC via (R)QMC

Recall that we described our ABC importance sampler as an algorithm that samples pairs $(\theta_n, x_n)$ from $q(\theta)q_\theta(x)$, where $x_n$ consists of datapoints generated from the model. In most ABC problems, using (R)QMC to generate the $\theta_n$ should be easy, but this should not be the case for the $x_n$’s. Indeed, the simulator used to generate datapoints from the model may be a complex black box, which may require a very large, or random, number of uniform variates. Thus, we contemplate from now on generating the $\theta_n$’s using (R)QMC. That is, $\theta_n = \Gamma(u_n)$, where $u_{1:N}$ is a QMC or RQMC sequence, and $\Gamma$ is a function such that $\Gamma(U)$, $U \sim U([0,1]^d)$, is distributed according to the proposal $q(\theta)$; and $x_n|\theta_n \sim q_{\theta_n}$ is a random variate. In other words, $(\theta_n, x_n)$ is a mixed sequence.

We already know from the previous section that an estimate based on a mixed sequence converges at the Monte Carlo rate, $O_P(N^{-1/2})$, but has a smaller asymptotic variance than the same estimate based on Monte Carlo. In fact, a similar result may be established directly for the actual (non-asymptotic) variance. Let $\hat{I}_N := \sum_{n=1}^{N} \varphi(\theta_n, x_n)/N$ be an empirical average for some measurable function $\varphi$. For simplicity, we assume here that the $\theta_n$’s are either random variates, or RQMC variates. That is, in both cases, $\theta_n \sim q$ marginally. Then

$$\text{Var}[\hat{I}_N] = \text{Var}\left[ \mathbb{E}\{\hat{I}_N|\theta_{1:N}\} \right] + \mathbb{E}\left[ \text{Var}\{\hat{I}_N|\theta_{1:N}\} \right]$$

$$= \text{Var}\left[ \frac{1}{N} \sum_{n=1}^{N} \mathbb{E}_{x_n \sim q_{\theta_n}} \{ \varphi(\theta_n, x_n)|\theta_n \} \right] + \frac{1}{N} \times \mathbb{E}_{\theta_n \sim q} \left[ \text{Var}_{x_n \sim q_{\theta_n}} \{ \varphi(\theta_n, x_n)|\theta_n \} \right]$$

(4)

The first term is $O(N^{-1})$ when the $\theta_n$’s are generated using Monte Carlo, and should be $o(N^{-1})$ under appropriate conditions when the $\theta_n$’s are a RQMC sequence. On the other hand, the second term is $O(N^{-1})$ in both cases. As a corrolary, the variance of $\hat{I}_N$ is smaller when using a mixed sequence, for $N$ large enough.

The point of the following sections is to generalize this basic result to various ABC estimates of interest.
4.1 Improved estimation of the normalization constant

We first consider the approximation of the normalization constant of the ABC posterior:

\[ Z_\epsilon = \int P_\theta (\delta(y,y^*) \leq \epsilon) p(\theta) d\theta = \int \hat{L}_\epsilon(x) q_\theta(x) p(\theta) dx d\theta. \]

Recall that, for the moment, we take \( x = y_{1:M} \), \( q_\theta(x) = \prod_{m=1}^M p(y_m|\theta) \) and

\[ \hat{L}_\epsilon(x) = \frac{1}{M} \sum_{m=1}^M \mathbb{1} \{ \delta(y_m,y^*) \leq \epsilon \}. \]

Thus, a natural estimator of \( Z_\epsilon \) is

\[ \hat{Z}_N := \frac{1}{N} \sum_{n=1}^N \frac{p(\theta_n)}{q(\theta_n)} \left[ \frac{1}{M} \sum_{m=1}^M \mathbb{1} \{ \delta(y_{n,m},y^*) \leq \epsilon \} \right] \] (5)

where the \( \theta_n \)'s are either a Monte Carlo or RQMC sample from the proposal \( q(\theta) \), and \( y_{n,m} \sim p(y|\theta_n) \) for \( n = 1, \ldots, N, \ m = 1, \ldots, M \).

When the \( \theta_n \)'s are a Monte Carlo sample, it is always best to take \( M = 1 \), as noted by Bormn et al. (2015). This may be seen by calculating both terms of decomposition (4) when applied to the estimator of the normalization constant \( \hat{Z}_N \):

\[ \text{Var} \left[ \mathbb{E} \{ \hat{Z}_N | \theta_{1:N} \} \right] = \frac{1}{N} \times \text{Var} \left[ \frac{p(\theta)}{q(\theta)} \mathbb{P}_\theta (\delta(y,y^*) \leq \epsilon) \right] \] (6)

\[ \mathbb{E} \left[ \text{Var} \{ \hat{Z}_N | \theta_{1:N} \} \right] = \frac{1}{NM} \times \int \left[ \frac{p(\theta)}{q(\theta)} \right]^2 \mathbb{P}_\theta (\delta(y,y^*) \leq \epsilon) \left\{ 1 - \mathbb{P}_\theta (\delta(y,y^*) \leq \epsilon) \right\} d\theta. \] (7)

Increasing \( M \) increases the CPU cost and decreases the variance of \( \hat{Z}_N \). To account for both simultaneously, we look at the adjusted variance, \( M \times \text{Var} \left[ \hat{Z}_N \right] \). From (6) and (7), we see that the adjusted variance increases with \( M \), hence the best CPU time vs error trade-off is obtained by taking \( M = 1 \).

Now, consider the situation where the \( \theta_n \)'s form a RQMC sequence. As noted in the previous section, (7) still holds in that case, however the first term of the decomposition should converge faster.

Proposition 1 Let \( f(\theta) = \{ p(\theta)/q(\theta) \}\mathbb{P}_\theta (\delta(y,y^*) \leq \epsilon) \), assume that \( \theta_n = \Gamma(u_n) \) where \( u_{1:N} \) is a scrambled \( (\lambda,t,m,d) \)-net, and assume that \( f \circ \Gamma \in L^2 \). Then,

\[ \text{Var} \left[ \mathbb{E} \{ \hat{Z}_N | \theta_{1:N} \} \right] = o \left( N^{-1} \right). \]

This result is a direct consequence of Corollary 1 of Gerber (2015) and the fact

\[ \mathbb{E} \{ \hat{Z}_N | \theta_{1:N} \} = \frac{1}{N} \sum_{n=1}^N f(\theta_n) = \frac{1}{N} \sum_{n=1}^N f \circ \Gamma(u_n). \]

It has two corollaries. First, the variance of \( \hat{Z}_N \) is smaller when using a RQMC sequence for the \( \theta_n \)'s (for \( N \) large enough). Second, in that case, the adjusted variance is such that \( M \text{Var}[\hat{Z}_N] = O(N^{-1}) \),
with a constant that does not depend on $M$. Thus taking \( M > 1 \) (within a reasonable range) should have basically no impact on the CPU time vs error trade-off in the RQMC case.

Taking \( M > 1 \) has the following advantage: it makes it possible to consistently estimate (7) with the quantity

$$\sigma^2(Z_\epsilon) := \frac{1}{N^2(M-1)} \sum_{n=1}^N \frac{p(\theta_n)^2}{q(\theta_n)^2} \hat{L}_\epsilon(x_n) \{1 - \hat{L}_\epsilon(x_n)\}. \tag{8}$$

where $\hat{L}_\epsilon(x_n) = M^{-1} \sum_{m=1}^M \mathbb{1}\{\delta(y_{n,m}, y^*) \leq \epsilon\}$. As (7) corresponds to the non-negligible part of the variance of $\hat{Z}_N$, this allows us to obtain asymptotic confidence intervals for $\hat{Z}_N$.

We have focused on the RQMC case for now on, but a similar result holds for QMC sequences. Note, however, that we cannot use directly decomposition (4) when the $\theta_n$’s are deterministic.

**Proposition 2** Assume that $f \circ \Gamma$ (where $f$ and $\Gamma$ are defined as in Proposition [7]) has a finite variation in the sense of Hardy and Krause, and that the ratio $p/q$ is upper-bounded, $p(\theta)/q(\theta) \leq C$, then

$$M \times \mathbb{E} \left[ (\hat{Z}_N - Z_\epsilon)^2 \right] = \mathcal{O}(N^{-1})$$

with a constant that does not depend on $M$. Furthermore, the mean square error above is smaller than in the Monte Carlo case, for $N$ large enough.

### 4.2 Improved estimation of general importance sampling estimators

We now turn to the analysis of general importance sampling estimators of the form

$$\hat{\phi}_N = \frac{\sum_{n=1}^N w_n \phi(\theta_n)}{\sum_{n=1}^N w_n}. \tag{9}$$

As these estimators are ratios, we cannot apply decomposition (4) directly. However, we may apply the following inequality, due to Agapiou et al. (2015):

$$\mathbb{E} \left\{ (\hat{\phi}_N - \mathbb{E}_{p_*} \phi)^2 \right\} \leq \frac{2}{Z_\epsilon^2} \left( \mathbb{E} \left\{ \frac{1}{N} \sum_{n=1}^N w_n \phi(\theta_n) - Z_\epsilon \mathbb{E}_{p_*} \phi \right\}^2 + \mathbb{E} \left\{ \frac{1}{N} \sum_{n=1}^N w_n - Z_\epsilon \right\}^2 \right)$$

provided $|\phi| \leq 1$. Both terms are mean square errors of empirical averages, and hence may be bounded directly using the results of the previous section. Thus, we see that, again, when the $\theta_n$ are generated with (R)QMC, the means square error of estimate $\hat{\phi}_N$ is $\mathcal{O}(M^{-1}N^{-1})$ as $N \to +\infty$. However, this inequality does not make it possible to compare the performance of our RQMC-ABC procedure with Monte Carlo-based ABC. For this, we now consider the asymptotic behavior of these estimators.

**Theorem 4** Let $\phi : \Theta \to \mathbb{R}$ be a bounded function, $\bar{\phi} = \phi - \mathbb{E}_{p_*} \phi$, $\hat{\phi}_N$ defined as [9], then, under the same conditions as Proposition [3] and assuming further that function $\mathbf{u} \to \phi(\Gamma(\mathbf{u})) f(\Gamma(\mathbf{u}))$ has a finite variation (in the sense of Hardy and Krause), one has that

$$N^{1/2} \left( \hat{\phi}_N - \mathbb{E}_{p_*} \phi \right) \xrightarrow{\mathcal{D}} \mathcal{N} \left( 0, \sigma_{\text{mixed}}^2(\phi) \right) ,$$

where, using the short-hand $b(\theta) = \mathbb{P}_\theta (\delta(y, y^*) \leq \epsilon)$,

$$\sigma_{\text{mixed}}^2(\phi) = \frac{1}{MZ_\epsilon^2} \int_{\Theta} \frac{p(\theta)^2}{q(\theta)} \bar{\phi}(\theta)^2 b(\theta) \{1 - b(\theta)\} d\theta. \tag{10}$$
Alternatively, if the parameter values \( \theta_n \) were generated through Monte Carlo sampling, one would obtain a similar central limit theorem, but with asymptotic variance

\[
\sigma^2_{MC}(\phi) = \frac{1}{Z^2} \int_{\Theta} \frac{p(\theta)^2}{q(\theta)} \phi(\theta)^2 \left[ \frac{b(\theta)(1 - b(\theta))}{M} + b(\theta)^2 \right] d\theta
\]

which is larger than or equal to \( \sigma^2_{\text{mixed}}(\phi) \).

As for the normalising constant, we observe that the adjusted (asymptotic) variance, i.e. \( M \times \sigma^2_{\text{mixed}}(\phi) \), is constant with respect to \( M \). Thus, taking \( M > 1 \) does not deteriorate the performance of the algorithm (in terms of variance relative to CPU time). And it makes it possible to estimate consistently the asymptotic variance (10) (and thus compute confidence intervals) using

\[
\hat{\sigma}^2_{\text{mixed}}(\phi) = \frac{1}{(Z_N)^2 N^2 (M - 1)} \sum_{n=1}^{N} \frac{p(\theta_n)^2}{q(\theta_n)} \left\{ \phi(\theta_n) - \hat{\phi}_N \right\}^2 \hat{L}_\epsilon(x_n) \left\{ 1 - \hat{L}_\epsilon(x_n) \right\}.
\]

5 Numerical examples

We illustrate in this section the improvement brought by (R)QMC through several numerical examples. Thus we compare three different approaches, all corresponding to Algorithm 1, but with particles generated using either Monte Carlo (ABC-IS), Quasi-Monte Carlo (ABC-QMC), or randomised QMC (ABC-RQMC).

We take \( q(\theta) = p(\theta) \), i.e. points are generated from the prior, and, unless explicitly stated, we take \( M = 1 \). (The problem of adaptively choosing \( q \) will be considered in the next section.)

In that case, weights \( w_n \) are either 0 or 1 (according to whether \( \delta(y_n, y^*) \leq \epsilon \)), and we set \( \epsilon \) so that the proportion of non-zero weights is close to some prespecified value, e.g. \( 10^{-3} \).

5.1 Toy model

The first model we consider is the toy model used in Marin et al. (2012) that tries to recover the mean of a superposition of two Gaussian distributions with identical mean and different variances:

\[
\theta \sim U([-10, 10]^d), \\
y | \theta \sim \frac{1}{2} \mathcal{N}(\theta; 0.1 I_d) + \frac{1}{2} \mathcal{N}(\theta; 0.001 I_d).
\]

The use of this model is motivated by the fact that the dimension of the model \( d \) can be scaled up easily. We set \( y^* = 0_d \) and \( \delta(y, y^*) = \|y - y^*\|_2 \).

We run the three considered algorithms with \( N = 10^6 \). Figure 2a shows that the MC and QMC approximations matches closely; for this plot, \( \epsilon = 0.01 \) (leading to a proportion of non-zero weights close to \( 10^{-3} \)), and \( d = 1 \).

Figure 3 compares the empirical variance (over 50 runs) obtained with the three considered approaches, as a function of \( \epsilon \), when estimating the expectation (left pane) and variance (right pane) of the ABC posterior. Again, \( N = 10^6 \), \( d = 1 \), and \( \epsilon \) is chosen so as to generate a proportion of non-zero weights that vary from 0 to 10%.
Figure 2: Left: Approximation of the posterior distribution based on $N = 10^6$ simulations and the threshold $\epsilon = 0.01$. Right: Adjusted variance (variance times $M$) of the normalization constant as a function of $M$: the dashed line corresponds to the variance estimator given by (8), the solid line corresponds to the empirical variance of the estimator based on 75 runs. Based on $N = 10^5$ simulations, $\epsilon = 1$, $d = 1$, and a QMC sequence for the $\theta_n$'s.

Figure 3: Variance of posterior estimates as $\epsilon$ varies (Left: ABC posterior mean; Right: ABC posterior variance). Plots based on 50 runs, with $N = 10^6$ simulations. The $x$–axis corresponds to a varying $\epsilon$, which is set so that the proportion of non-zero weights (i.e. the proportion of simulated $y_n$ such that $\delta(y_n, y^*) \leq \epsilon$) varies from 0 to 10%.
We observe a significant variance reduction when using either QMC or RQMC and for not too small values of $\epsilon$, but the variance reduction vanishes as $\epsilon \to 0$. However, interestingly, the variance reduction (again for not too small values of $\epsilon$) remains significant when we increase the dimension, see Figures 4. (For $d > 1$, the considered estimated quantity is the expectation of the average of the $d$ components of $\theta$ with respect to the ABC posterior.)

Finally, we consider increasing $M$, so as to be able to estimate the variance of a given ABC estimate from a single run of Algorithm 1, when using (R)QMC, as explained at the end of Section 4.1. The considered estimate is that of the normalising constant of the ABC posterior. We see that the variance estimate is fairly stable even for small values of $M$, and that it is close to the actual variance (over 75 runs) of the estimate as can be seen in Figure 2b.

Note that both quantities are multiplied by $M$ in this plot. This allows us to check that the adjusted variance (accounting for CPU time) remains constant, as expected. As already explained, this means that taking $M > 1$ is not sub-optimal (in terms of the variance vs CPU time trade-off), while it allows us to estimate the variance of any estimate obtained from the (R)QMC version of Algorithm 1.

5.2 Lotka-Volterra-Model

The Lotka-Volterra model, see Toni et al. (2009), is commonly used in population dynamics to study the interaction in predator-prey models, for example. The model is characterized by the respective size of the populations evolving over time and denoted by $(X_1, X_2)$, taking values in $\mathbb{Z}^2$.

There are three possible transitions: the prey (denoted by $X_1$) may grow by one entity with rate $\alpha$, a predation may happen with rate $\beta$, that reduces the prey by one unit and increases the predator population (denoted by $X_2$) by one unit, or the predator may die with rate $\gamma$. The system is summarized by the following rate equations:

$$(X_1, X_2) \xrightarrow{\alpha} (X_1 + 1, X_2),$$
$$(X_1, X_2) \xrightarrow{\beta} (X_1 - 1, X_2 + 1),$$
$$(X_1, X_2) \xrightarrow{\gamma} (X_1, X_2 - 1),$$

with the corresponding hazard rates $\alpha X_1$, $\beta X_1 X_2$ and $\gamma X_2$, respectively. The hazard rates characterize the instantaneous probability that the system changes to a new state. The parameter of the model is $\theta = (\alpha, \beta, \gamma)$. The initial population is fixed to (50, 100).
We simulate from the model using Gillespie’s algorithm, see [Toni et al. 2009], for $T = 30$ time steps, and record the size of the population at times $t_i = 2i$, where $i = 0, \cdots, 15$. This gives two discrete time series of length 16. As a distance function for comparing our true observation and the pseudo-observations, we use the Euclidean norm $\| \cdot \|_2$ applied to the differences of the series. As a prior we use $u \sim U[-6, 2]^3$, which is then transformed to $\theta = \exp(u)$.

As in the previous section, we compare the empirical variance over 50 runs of a given estimate obtained from the different approaches. The estimated quantity is the expectation of $(\alpha + \beta + \gamma)/3$ with respect to the ABC posterior.

![Figure 5: Variance of the mean and variance estimator for the Lotka–Volterra model. Plots based on 50 repetitions of $10^5$ simulations from the prior and the model. The accepted observations correspond to quantiles based on the smallest distances $\delta(y_n, y^*)$. Left: Variance of the posterior variance estimator. Right: Variance of the posterior variance estimator](image)

We observe the same phenomenon that in the previous example: the variance reduction brought by either QMC or RQMC is significant for not too small values of $\epsilon$, but it vanishes as $\epsilon \to 0$.

### 5.3 Tuberculosis mutation

The following application is based on the estimation of tuberculosis reproduction rates as in [Tanaka et al. 2006]. The interest lies in recovering the posterior distribution of birth, death and mutation rates $(\alpha, \beta, \gamma)$ of a tuberculosis population that has been recorded in San Francisco over a period from 1991 to 1992.

The simulator of the model is based on an underlying continuous time Markov process where $t$ denotes the time and $N(t)$ denotes the size of the population. Starting from one single bacterium the individual can either replicate itself with rate $\alpha$, die with rate $\gamma$ or mutate to a new genotype with rate $\beta$. The number of bacteria having the same genotype is recorded at every step and the simulation is run forward until a size of $N(t) = 10^4$ has been obtained. At every step in the simulation a bacterium is chosen uniformly at random and one of the three events $(\alpha, \beta, \gamma)$ is applied to it. After simulating a population of $10^4$ bacteria, the simulation is stopped and a subpopulation of 473 bacteria is sampled. The ensuing population is characterized by the cluster size of bacteria that have the same genotype. The data is available in Table I. For instance, there were 282 clusters with only one bacterium with the same genotype and there were 20 clusters that contained two bacteria with the same genotype.
Cluster size | 1 | 2 | 3 | 4 | 5 | 8 | 10 | 15 | 23 | 30
Number of clusters | 282 | 20 | 13 | 4 | 2 | 1 | 1 | 1 | 1 | 1

Table 1: Tuberculosis bacteria genotype data

The parameters must satisfy the conditions $\alpha + \beta + \gamma = 1$, $0 \leq \alpha, \beta, \gamma \leq 1$, and $\alpha > \gamma$. (The last constraint prevents the population from dying out.) Thus, we let $\beta = 1 - \alpha - \gamma$, and assign a uniform prior to $(\alpha, \gamma)$, subject to $\alpha > \gamma$. Tanaka et al. (2006) used as a summary statistic for the data the quantities $y = (g/473, 1 - \sum_i(n_i/473)^2)$, where $g$ denotes the number of distinct clusters in the sample and $n_i$ is the number of observed bacteria in the $i$th genotype cluster. The distance between a pseudo observation and the observed data is finally calculated as the Euclidean distance between $y$ and $y^\star$. Figure 6(a) shows the recovered posterior distribution after application of a sequential sampling approach, that is described in section 7. We see our method, denoted by QMC and the method of Del Moral et al. (2012), denoted by Del Moral recover the same posterior distribution. There remain some artifacts in the second method, due to a slightly higher acceptance threshold $\epsilon = 0.12$ compared to $\epsilon = 0.08$ as in the QMC approach. We estimate the ABC posterior expectation of $(\alpha + \gamma)/2$ and then compare the empirical variance of this estimator. The result of the repeated simulation of this estimator is shown in Figure 6(b), where we show the value of $\text{Var}_{MC} / \text{Var}_{(R)QMC}$, where $\text{Var}_{MC}$ is the variance of the posterior estimator based on a MC sequence. This quantity allows to assess the variance reduction factor as a function of the acceptance threshold. Again, we observe a declining variance reduction as $\epsilon \to 0$. Nevertheless, the variance reduction even for the smallest acceptance threshold is still of factor 1.5, which means that we need 33% fewer simulations in order to achieve the same precision of the estimator.

![Figure 6](image)

(a)

(b)

Figure 6: Left: Posterior distribution of the tuberculosis mutation model. The x–axis corresponds to birth rate $\alpha$, the y–axis corresponds to the death rate $\beta$. Right: Variance reduction factors (computed from 50 runs) as a function of the proportion of non-zero weights.

5.4 Concluding remarks

As predicted by the theory, we observed that using QMC (or RQMC) to generate the parameter values (in Algorithm 1) always reduce the variance of ABC estimates. However, the variance reduction becomes small when $\epsilon \to 0$. But it should be noted that any static ABC algorithm, such as Algorithm 1 becomes very wasteful when $\epsilon$ is small, as most simulated datapoints lies outside the ball defined by the constraint $\delta(y, y^\star) \leq \epsilon$ in such a case. In order to take $\epsilon$ smaller and
smaller, it seems to make more sense to progressively refine the proposal distribution, based on past simulations. This is the point of sequential ABC algorithms, which we discuss in the next two sections.

6 Sequential ABC

6.1 Adaptive importance sampling

One major drawback of Algorithm 1 is that the quality of the approximation in \( \text{(2)} \) depends on how well the proposal distribution \( q(\theta) \) matches the target distribution \( p(\theta) \). If, for example, the proposal is very flat and the target is spiky due to a small value of \( \epsilon \), only a small number of particles will cover the region of interest. The idea of sequential ABC algorithms is therefore to sequentially decrease \( \epsilon \) over a range of time steps \( t \in 0 : T \) while adapting the proposal distribution \( q_t(\theta) \) so as to make it closer and closer to the true posterior.

In the current setting we will use a flexible parametric approximation \( q_t(\theta) \) of the ABC posterior \( p_{\epsilon_t}(\theta) \), that is estimated from the the samples \( (\theta_{t-1}^n, x_{t-1}^n, w_{t-1}^n)_{n \in 1:N} \). This distribution \( q_t(\theta) \) is then used to simulate new particles \( (\theta_t^t)_{n \in 1:N} \). The corresponding algorithm is given as pseudo-code in Algorithm 2.

\[\text{Input:} \text{ Observed } y^*, \text{ prior distribution } p(\theta), \text{ simulator } q_\theta(x), \text{ initial threshold } \epsilon_0, \text{ number of simulations } N, \text{ weighting procedure } \hat{L}_\epsilon(x).\]

\[\text{Result:} \text{ Set of weighted samples } (\theta_t^t, x_t^t, w_t^t)_{n \in 1:N, t \in 0:T}.\]

\[\text{for } n = 1 \text{ to } N \text{ do} \]
\[\text{Sample } \theta_0^n \sim p(\theta); \]
\[\text{set } w_0^n = 1; \]
\[\text{end}\]

\[\text{for } t = 1 \text{ to } T \text{ do} \]
\[\text{Set } \epsilon_t \text{ and } q_t(\theta) \text{ based on } (\theta_{t-1}^n, x_{t-1}^n, w_{t-1}^n)_{n \in 1:N}; \]
\[\text{for } n = 1 \text{ to } N \text{ do} \]
\[\text{Sample } \theta_t^n \sim q_t(\theta); \]
\[\text{Sample } x_t^n \sim q_\theta^n(x); \]
\[\text{Set } w_t^n = p(\theta^n_t)\hat{L}_\epsilon(x^n_t)/q_t(\theta^n_t); \]
\[\text{end}\]
\[\text{end}\]

**Algorithm 2:** ABC adaptive importance sampling algorithm

6.2 Adapting the proposal \( q_t \)

6.2.1 Gaussian proposal

The simplest strategy one may think of to adapt \( q_t \) is to set it to a Gaussian fit of the previous weighted sample. Although basic, we shall see that this approach tends to work well in practice, unless of course the actual posterior is severely multimodal.

6.2.2 Mixture of \( N \) components

The SMC sampler of Sisson et al. (2009) may be viewed as a particular version of Algorithm 2, where \( q_t \) is set to a mixture of \( N \) Gaussian components centred on the \( N \) previous particles \( \theta_{t-1}^t \),
with covariance matrix $\hat{\Sigma}^{-1}$ set to twice the empirical covariance of these particles. The proposal distribution reads

$$q_t(\theta) = \frac{\sum_{n=1}^{N} w_{n}^{-1} N(\theta | \theta_n^{-1}, 2\hat{\Sigma}^{-1})}{\sum_{n=1}^{N} w_{n}^{-1}}.$$ 

This results in an algorithm of complexity $O(N^2)$ since for every proposed new particle $\theta_n^t$, computing the corresponding weight involves a sum over $N$ terms.

### 6.2.3 Mixture proposal with a small number of components

As an intermediate solution between a single Gaussian distribution and a mixture of $N$ Gaussian distributions, we suggest to use a Gaussian mixture with a small number of components. We suggest to estimate the mixture via a Variational Bayesian procedure, see Blei et al. (2016), but other methods as Expectation Maximization could also be used. The proposal distribution reads

$$q_t(\theta) = \sum_{j=1}^{J} \alpha_j^{t-1} N(\theta | \mu_j^{t-1}, \lambda \hat{\Sigma}_j^{t-1}),$$

where $\alpha_j^{t-1}$, $\mu_j^{t-1}$, and $\hat{\Sigma}_j^{t-1}$ denote respectively the weight, mean, and covariance matrix of cluster $j$ estimated at iteration $t - 1$. Again, we artificially inflate the covariances with a factor $\lambda > 1$ in order to put more mass in the tails of the proposal distribution. Regarding $J$, we may either fix it arbitrarily or use the Variational Bayesian approach to choose it automatically.

In order to generate QMC or RQMC points from such a mixture distribution, we set the number of samples for each cluster $j$ to $N_j^t = \left\lfloor \frac{1}{\alpha_j^{t-1} N} \right\rfloor$ and potentially adjust $N_j^t$ as to make sure that $\sum_j N_j^t = N$ holds. For each cluster $j$, a (R)QMC sequence of length $N_j^t$ is generated and transformed to the sample of a Gaussian distribution $N(\theta | \mu_j^{t-1}, \lambda \hat{\Sigma}_j^{t-1})$. This is achieved via the transformation of the (R)QMC sequence $(u_n)_{n \in 1:N_j^t}$ via the component-wise quantile function $\Phi^{-1}(\cdot): \theta_n^t = \mu_j^{t-1} + C_{t-1} \Phi^{-1}(u_n)$, where $C_{t-1}$ is the Cholesky triangle of the covariance matrix: $C_t C_t^T = \lambda \hat{\Sigma}_j^{t-1}$.

This approach has the following advantages. First, we maintain flexibility by allowing to cover several modes, as the posterior distribution might be multi-modal. Second, the use of a limited number of clusters makes sure that we can benefit from the better coverage of the space that comes from the use of (R)QMC sequences. Using only a small number of clusters preserves the structure of the (R)QMC point set. In contrast, using the approach of Sisson et al. (2009) would destroy the properties of the low discrepancy or scrambled net sequences and hence the variance reduction that comes from the (R)QMC sequence could vanish. (This has been found as a result of our simulation studies, not shown here.)

### 6.3 Adapting simultaneously $\epsilon_t$ and the number of simulations per parameter

As discussed in Section 2.2 the weights $\hat{L}_{\epsilon_t}(x_n^t)$ are unbiased estimators of the probabilities $P_{\theta_n^t}(\delta(y^*, y) \leq \epsilon_t)$, which may be obtained in two ways: (a) as an average over a fixed number $M$ of simulations; or (b) as a function of the number of simulations required so that $k$ of them are at a $\epsilon$ distance of $y^*$; that random number follows a negative binomial distribution.

So far, we have focused on (a), and even took $M = 1$ in our first set of numerical examples in Section 5. If we use this strategy, we may follow Del Moral et al. (2012) in adapting $\epsilon_t$ according to the ESS (effective sample size, Kong et al. 1994); i.e. at iteration $t$, once we have simulated
the $\theta^n_t$'s and the $x^n_t$'s, we solve numerically (using bisection) in $\epsilon_t$ the equation $\text{ESS} = \alpha N$, for $\alpha \in (0, 1)$, where

$$\text{ESS} = \frac{\left(\sum_{n=1}^{N} w^n_t\right)^2}{\sum_{n=1}^{N} (w^n_t)^2}$$

and $w^n_t = p(\theta^n_t)\hat{L}_\epsilon(x^n_t)/q(\theta^n_t)$, $\hat{L}_\epsilon(x^n_t) = M^{-1} \sum_{m=1}^{M} 1\{\delta(y^*_m, y^n_{n,m}) \leq \epsilon_t\}$.

This approach usually works well during the first iterations of Algorithm 2, but it is bound to collapse as $\epsilon$ gets too small: as $\epsilon \to 0$, $P_{\theta_t}(\delta(y^*, y) \leq \epsilon) \to 0$ whatever $\theta$, and as result most weights $w^n_t$ become zero when $\epsilon_t$ is too small. One remedy is to set $M$ to a much larger value, so that weights take much longer to collapse. However, this is expensive and wasteful, given that the first iterations would work well with a much smaller $M$.

In that sequential context, the negative binomial strategy for computing the weights becomes appealing, as it makes it possible to adapt automatically the CPU effort to a given $\epsilon$: we may decrease $\epsilon_t$ at each iteration, while ensuring that the variance of the weights (as estimates of the probabilities $P_{\theta_t}(\delta(y^*, y) \leq \epsilon_t)$) does not blow up. Of course, the price to pay is that iterations become more and more expensive.

In practice, we found that this approach was unwieldy during the first iterations of the algorithm: during that time, a few simulated parameters $\theta^n_t$ are such that the corresponding probability that $\delta(y^*, y) \leq \epsilon_t$ is much smaller than for the other particles. As a result, the negative binomial estimate requires generating a lot of observations for those particles, which typically gets discarded later.

Thus, in the end, we recommend the following hybrid strategy:

- At iterations $t = 0$ to $t = T_1$ (say $T_1 = 10$), use the ‘fixed $M$’ (say $M = 10$) strategy to compute the weights, and adapt $\epsilon_t$ using the ESS.
- At iterations $t > T_1$, switch to the negative binomial strategy for computing the weights, and adapt $\epsilon_t$ as follows: set it to the median of the distance values $\delta(y^*, y_n)$ where the $y_n$’s denote here all the artificial observations generating during the previous iteration such that $\delta(y^*, y_n) \leq \epsilon_{t-1}$. Stop when $\epsilon_t$ gets below a certain target value $\epsilon^*$.

7 Numerical illustration of the sequential procedure

7.1 Toy model

We return to the toy model of Section 5.1, taking this time $d = 3$. We compare five algorithms: three versions of Algorithm 2 with the $\theta^n_t$’s generated using, respectively, Monte Carlo, Quasi-Monte Carlo, and RQMC; the sequential ABC algorithm of Sisson et al. (2009), which (as explained previously) is essentially Algorithm 2 with a mixture proposal with $N$ components; and finally the algorithm of Del Moral et al. (2012). (The algorithm of Del Moral et al. (2012) generates the $\theta^n_t$ by evolving the particles resampled at the previous iteration through a Markov kernel; see the paper for more details.)

Regarding the adaptive choice of $\epsilon_t$, we use the hybrid strategy outlined in the previous section for our MC, QMC and RQMC algorithms, we use the ESS-based strategy for Del Moral et al. (2012)’s algorithm, and we use the following strategy for Sisson et al. (2009)’s: $\epsilon_t$ is set to the median of the distances $\delta(y^*, y_n)$ computed at the previous iteration. For all these algorithms, we set $M = 10$.

For this toy model, we simply consider the basic strategy for adapting $q_t$ outlined in Section 6.2.1 i.e. $q_t$ is a Gaussian fit to the previous set of particles. The five algorithms are run with
either \( N = 10^3 \) (Figure 7) or \( N = 10^4 \) particles (Figure 8); in both cases the algorithms are stopped when \( \epsilon_t \leq \epsilon^* = 1 \). In both figures, we plot the adjusted MSE at iteration \( t \) as a function of \( \epsilon_t \), where the adjusted MSE is the empirical MSE of a given estimate (over 50 runs) times the number of observations generated from the model up to time \( t \). The adjusted MSE make it possible to account for the different running times of the algorithms. See also Table 2 for a direct comparison in terms of both CPU effort and MSE.

The considered estimates are the same as in Section 5.1, i.e. the ABC posterior expectation and variance of \( \bar{\theta} \), the average of the components of vector \( \theta \). At least for posterior expectations, we see that the QMC and RQMC versions outperform the MC version of our algorithm, which in turn outperforms the sequential ABC algorithms of Sisson et al. [2009] and Del Moral et al. [2012].

Figure 7: three-dimensional Gaussian toy example. Algorithms run with \( N = 10^3 \) particles. Adjusted variance (as defined in the text) at iteration \( t \), as function of \( \epsilon_t \), for the following posterior estimate: exception (left) and variance (right) of \( \bar{\theta} = (\theta_1 + \theta_2 + \theta_3)/3 \).

Figure 8: Same as Figure 7 except algorithms are run with \( N = 10^4 \) particles.

Table 2: Toy example, performance of the five considered sequential algorithms at the final iteration $T$, for $N = 10^3$ particles

### 7.2 Bimodal Gaussian distribution

In order to illustrate the flexibility that comes from using a mixture of Gaussians for the proposal we consider a model that yields a multi-modal posterior:

$$
\theta \sim U([-10, 10]^d),
$$

$$
y_i \overset{iid}{\sim} \frac{1}{2} N(\theta, I_d) + \frac{1}{2} N(-\theta, I_d), \quad i = 1, \ldots, 100.
$$

We simulate $y^*$ from the model. The model is not identifiable and thus generates a bimodal posterior. Regarding the distance $\delta$, we follow the idea of [Bernton et al. (2017)] and use the optimal transport distance between $y$ and $y^*$, more specifically the earth-movers-distance.

Figure 9: Simulation for the bimodal distribution. Left: recovered posterior distribution. Right: average (over 50 runs) of cumulative number of simulations according to acceptance threshold; algorithms were run with $N = 10^3$ particles.
Figure 10: Same plot as in Figure 7 for the bimodal example and \( N = 10^3 \).

We set \( \epsilon^\star = 5 \times 10^{-3} \). This value has been chosen as before as a small quantile of the realized distances after \( 10^6 \) simulations from the prior and the simulator. The recovered posterior is shown in Figure 9a. Figure 9b illustrates the adaptivity in the simulation from the simulator achieved via the negative binomial approach. As the threshold becomes smaller and smaller, the number of necessary simulations start to increase severely. In the end, the number of necessary simulations of the different methods catch up with each other. Still, the approaches based on (R)QMC achieve a lower variance of the estimator as is illustrated in Figures 10a and 10b.

7.3 Tuberculosis mutation

We now return to the tuberculosis example presented in Section 5.3; we set the target value \( \epsilon^\star = 0.01 \), and restrict the CPU budget to \( 10^6 \) simulations from the model, as these simulations are computationally intensive. We see that again the QMC approach performs best in terms of number of simulations needed and also in terms of variance times computational budget; see Figures 11a and 11b and Table 3. The approach of Sisson et al. (2009) exceeds the total computation budget and thus does not reach the fixed threshold. Figures 11a and 11b illustrate the effect of the hybrid strategy for adapting \( \epsilon \) and the number of simulations per parameter value (Section 6.3). The kink in the lines for the adaptive importance sampling approaches corresponds to the moment when the weighting is obtained via the negative binomial distribution.

8.1 Proofs of main results

8.1.1 Proof of Corollary

For the mixed sequences we have

\[
\lim_{N \to \infty} \frac{1}{N} \sum_{k=1}^{N} \sigma^2_{k,\text{qmc-mixed}} = C^2_{\text{qmc-mixed}}
\]

and for the Monte Carlo estimate we have

\[
\lim_{N \to \infty} \frac{1}{N} \sum_{k=1}^{N} \sigma^2_{k,\text{mc}} = C^2_{\text{mc}}
\]

where

\[
C^2_{\text{qmc-mixed}} = \int_{[0,1]^s} f(x)f(x)^T \, dx - \int_{[0,1]^d} \left( \int_{[0,1]^{s-d}} f(u) \, dX^{d+1:s} \right) \left( \int_{[0,1]^{s-d}} f(u) \, dX^{d+1:s} \right)^T \, dq^{1:d}
\]
We must show that
\[
\left( \int_{[0,1]^s} f(x)dx \right) \left( \int_{[0,1]^s} f(x)dx \right)^T \leq \int_{[0,1]^{s-d}} \left( \int_{[0,1]^{s-d}} f(u)dX^{d+1:s} \right) \left( \int_{[0,1]^{s-d}} f(u)dX^{d+1:s} \right)^T dq^{1:d},
\]
in the sense of positive definite matrices. This inequality holds in the univariate case due to the Cauchy-Schwarz inequality. In the multivariate case, let \( \int_{[0,1]^{s-d}} f(u^k)dX^{d+1:s} = A(q^{1:d}) \). We rewrite:
\[
\int_{[0,1]^d} A(q^{1:d}) dq^{1:d} \int_{[0,1]^d} A(q^{1:d})^T dq^{1:d} \leq \int_{[0,1]^d} A(q^{1:d}) A(q^{1:d})^T dq^{1:d}.
\]
In order to check the positive definiteness let \( v \in \mathbb{R}^s \). We check
\[
v^T \int_{[0,1]^d} A(q^{1:d}) dq^{1:d} \int_{[0,1]^d} A(q^{1:d})^T dq^{1:d} v \leq v^T \int_{[0,1]^d} A(q^{1:d}) A(q^{1:d})^T dq^{1:d} v,
\]
\[
\int_{[0,1]^d} v^T A(q^{1:d}) dq^{1:d} \int_{[0,1]^d} A(q^{1:d})^T vdq^{1:d} \leq \int_{[0,1]^d} v^T A(q^{1:d}) A(q^{1:d})^T vdq^{1:d}.
\]
While noting that \( v^T A(q^{1:d}) \in \mathbb{R} \) and \( A(q^{1:d})^T v \in \mathbb{R}, \forall v \in \mathbb{R}^s \) we are back in the univariate case and the inequality holds. \( \square \)

### 8.1.2 Proof of Theorem 3

The statement of the theorem is equivalent to \( \lim_{N \to \infty} |P(T_N \leq t) - P(Z \leq t)| = 0 \) for all \( t \in \mathbb{R}^s \), \( T_N = N^{1/2} S_{N}^{RQMC} \), and \( Z \) a random variable distributed according to the Gaussian limit.

When conditioning on the random element \( V \) in the RQMC sequence, we have that
\[
\lim_{N \to \infty} P(T_N \leq t|V = v) = P(Z \leq t)
\]
for almost all \( v \), by Theorem 2 as a RQMC sequence is a QMC sequence with probability one. Furthermore, \( |P(T_N \leq t|V = v)| \leq 1 \), thus the function is dominated. For all \( N \) we have
\[
|P(T_N \leq t) - P(Z \leq t)| = \left| \int_{B} \left\{ P(T_N \leq t|V = v) - P(Z \leq t) \right\} dP(v) \right|.
\]
\[
\leq \int_{B} |P(T_N \leq t|b) - P(Z \leq t)| dP(v).
\]
And
\[
\lim_{N \to \infty} \int_{B} |P(T_N \leq t|V = v) - P(Z \leq t)| dP(v) = 0,
\]
due to the dominated convergence theorem. Therefore
\[
\lim_{N \to \infty} |P(T_N \leq t) - P(Z \leq t)| = 0.
\] \( \square \)
8.1.3 Proof of Proposition 2

Since the \( \theta_n \)'s are deterministic,

\[
\mathbb{E}\left[ \hat{Z}_N \right] = \frac{1}{N} \sum_{n=1}^{N} \frac{p(\theta_n)}{q(\theta_n)} \mathbb{P}_{\theta_n} (\delta(y,y^*) \leq \epsilon) = \frac{1}{N} \sum_{n=1}^{N} f(\theta_n)
\]

\[
\text{Var}[\hat{Z}_N] = \frac{1}{MN^2} \sum_{n=1}^{N} \left\{ \frac{p(\theta_n)}{q(\theta_n)} \right\}^2 \mathbb{P}_{\theta_n} (\delta(y,y^*) \leq \epsilon) \{1 - \mathbb{P}_{\theta_n} (\delta(y,y^*) \leq \epsilon)\}
\]

and

\[
\left| \mathbb{E}\left[ \hat{Z}_N \right] - Z_\epsilon \right| = O(N^{-1}) \quad \text{for any } \tau > 0, \text{ by Koksma-Hlawka inequality.}
\]

By the standard decomposition of the mean square error:

\[
\mathbb{E}\left[ (\hat{Z}_N - Z_\epsilon)^2 \right] = \left( \mathbb{E}\left[ \hat{Z}_N \right] - Z_\epsilon \right)^2 + \text{Var}\left[ \hat{Z}_N \right]
\]

and since \( p(\theta_n)/q(\theta_n) \leq C \), we see that the MSE times \( M \) is \( O(N^{-1}) \).

8.1.4 Proof of Theorem 4

One has:

\[
\left( \hat{\phi}_N - \mathbb{E}_{p_\epsilon} \phi \right) = \left( \frac{\sum_{n=1}^{N} w_n \phi(\theta_n)}{\sum_{n=1}^{N} w_n} - \mathbb{E}_{p_\epsilon} \phi \right) = \frac{N^{-1} \sum_{n=1}^{N} w_n \bar{\phi}(\theta_n)}{N^{-1} \sum_{n=1}^{N} w_n}
\]

where \( \bar{\phi} = \phi - \mathbb{E}_{p_\epsilon} \phi \). Since the denominator converges almost surely to \( Z_\epsilon \), and the numerator (times \( N^{1/2} \)) converges to a Gaussian limit (per Theorem 2), we may apply Slutsky’s theorem to obtain the desired result.

More precisely, the numerator has a null expectation, and is such that

\[
N^{-1/2} \sum_{n=1}^{N} w_n \bar{\phi}(\theta_n) \overset{L}{\to} N \left( 0, \tau^2(\phi) \right)
\]

where

\[
\tau^2(\phi) = \int_{\Theta} \frac{p(\theta)^2}{q(\theta)} \phi(\theta) \frac{b(\theta)}{M} \left\{1 - b(\theta)\right\} d\theta
\]

again by direct application of Theorem 2 and using the fact that, for a fixed \( \theta_n \),

\[
\text{Var}_{x_n \sim q_{\theta_n}} [\hat{L}_\epsilon(x_n)] = \frac{b(\theta_n)}{M} \left\{1 - b(\theta_n)\right\}
\]

with \( b(\theta) = \mathbb{P}_{\theta} (\delta(y,y^*) \leq \epsilon) \).

\( \Box \)
